## **Acknowledgements**

I would like to thank my supervisor, Kitty Milliken, and the members of my thesis committee, Brian Horton and Ron Steel, for help and guidance during my research and feedback that improved the quality of my thesis. A summer research assistanceship provided by Brian Horton to analyze detrital zircons for his project with Ecopetrol proved to be an invaluable learning experience and greatly improved the quality and speed of my analyses. I would also like thank James Donelly of the Core Research Center for assistance in accessing and sampling cores, Bill Galloway for providing access to the Gulf of Mexico Basin Depositional Synthesis project which was a great help in locating cores to sample, John Breyer for leading an excellent field trip to Bee Bluff, the Briscoe Ranch and Martin Marrietta Materials for permission to take samples from their property, James Connelly for teaching me zircon systematics, Todd Housh (deceased) for guidance on analyzing detrital zircons on the Isoprobe and assistance in data reduction. Discussions with Bill Galloway, Tim Lawton, and Bill Dickinson refined many of my thoughts and helped me identify some areas that I needed to rethink. Funding for this research was provided by the AAPG Grants-in-Aid program, the Geological Society of America Graduate Student Research Grants, the Jackson School of Geosciences and the Geology Foundation of the University of Texas at Austin.

## **Abstract**

# **Provenance of the South Texas Paleocene-Eocene Wilcox Group, Western Gulf of Mexico Basin: Insights from Sandstone Modal Compositions and Detrital Zircon Geochronology**

Glen Nelson Mackey, III, MSGeoSci  
The University of Texas at Austin, 2009

Supervisor: Kitty L. Milliken

Sandstone modal compositions and detrital zircon U-Pb analysis of the Paleocene-Eocene Wilcox Group of the southern Gulf Coast of Texas indicate long-distance sediment transport primarily from volcanic and basement sources to the west, northwest and southwest.

The Wilcox Group of south Texas represents the earliest series of major post-Cretaceous pulses of sand deposition along the western margin of the Gulf of Mexico (GoM). Laramide basement uplifts have long been held to be the provenance of the Wilcox Group, implying that initiation of basement uplifts was the driving factor for this transition from carbonate sedimentation to clastic deposition. To determine the provenance of the Wilcox Group and test this conventional hypothesis, 40 thin sections were point-counted using the Gazzi-Dickinson method to determine sandstone

composition and 10 detrital zircon samples were analyzed by LA-ICP-MS to determine U-Pb age spectra for each of the sampled areas.

Modal data for sand grain populations suggest mixed sources including basement rocks, magmatic arc rocks and subordinate sedimentary rocks for the Wilcox Group. Zircon age spectra for these sandstones reveal a complex grain assemblage derived from older sediments and crystalline rocks ranging in age from Archean to Cenozoic. Sediment was primarily derived from Laramide uplifted crystalline blocks of the central and southern Rocky Mountains, the Cordilleran arc of western North America, and arc related extrusive and intrusive igneous rock of northern Mexico. Comparisons of Upper and Lower Wilcox zircon age spectra show that more arc related material was deposited in the Lower Wilcox, whereas more basement material was deposited in the Upper Wilcox.

## INTRODUCTION

Passive margins commonly draw sediment from a vast area. One only needs to consider the modern Mississippi river to observe the scale and diversity of sediment sources in a passive-margin drainage system/network. In the case of the Mississippi River, the detrital zircon age spectra of modern sediment taken from the river mouth match well the known geologic complexity of the river drainage (Iizuka et al., 2005), suggesting that detrital zircons from an ancient passive margin will be equally informative concerning the lithologies and geographic extent of sediment sources.

Understanding the provenance of sediment in basins far from areas of uplift can address several tectonic and sedimentological questions. If specific sources can be identified, then a paleogeographic picture of uplifts and drainages can be developed for the region, as well as a notion of how this picture changes through time if samples are available from several stratigraphic levels. On the other hand, if high-resolution uplift histories of the sources areas have already been determined, then it is possible to assess whether tectonics are responsible for pulses of sedimentary deposition, and if so, how much lag time there is between uplift and erosion in the source area and deposition in the basin (e.g., Crabaugh, 2001).

The Gulf of Mexico (GoM) sedimentary basin contains a prolonged record of North American denudation (Winker, 1982; Galloway, 2008). A key transition within this record is the shift from dominantly carbonate sedimentation to siliciclastic deposition that occurred along the western Gulf margin during the Late Cretaceous to Paleocene. The Paleocene-Eocene Wilcox Group of south Texas represents the earliest major pulse of sand deposition along this segment of the margin, though much of the previous thought on its provenance has been based solely on the tectonic history of North America

(Winker, 1982). There are several possible source areas for the Wilcox Group: 1) Laramide uplifts of the Rocky Mountains, 2) Appalachian uplifts, 3) volcanic rocks in northern Mexico, 4) magmatic rocks of the Cordilleran arc, and 5) strata of the mid-continent High Plains. The goal of this study is to test these possible source areas and determine the provenance of the Wilcox Group using sandstone petrography and detrital zircon geochronology.

### **Geological Setting**

The Paleocene-Eocene (60.6-49.0 Ma (Crabaugh, 2001 and references therein)) Wilcox Group of the Texas Gulf Coast records the first major deliveries of Cenozoic clastic wedges to the northwest Gulf of Mexico in the form of large delta systems (Galloway, 2008), comparable in size to the modern Mississippi system (Fisher and McGowen, 1967), with accompanying coastal plain and fluvial systems. Overall southeastward progradation of the shelf edge and continental margin during this period was approximately 150-200 km beyond Cretaceous reef deposits that marked the earlier shelf edge (Galloway et al., 2000). Extensive petroleum and mineral resource exploration has led to a very complex stratigraphic nomenclature system for the Wilcox group (e.g., Hargis, 1985; Galloway and Williams, 1991; Xue and Galloway, 1993, 1995), so I will use the simplified lithostratigraphic nomenclature system of Hargis (1996) and divide the Wilcox group into three informal subunits, the Upper, Middle and Lower (Figure 1). High-resolution biostratigraphic calibration of the Wilcox group to the Cenozoic time scale by Crabaugh (2001) and Crabaugh and Elsik (2000) give the following ages for each subunit: Lower Wilcox, 60.6-57.5 Ma; Middle Wilcox, 57.5-54.8 Ma; and Upper Wilcox, 54.8-49.0 Ma. Based on accessed uncertainties in

Figure 1. Chronology of Cenozoic Gulf of Mexico deposition after Galloway (2001).  
The right hand bar chart plots the volumetric rate of sediment accumulation in combined shore-zone and delta systems of each episode. \* = extensive marine condensed section characterized by very low accumulation rates.

correlating biostratigraphic datums in the Wilcox Group to absolute biozone ages, Crabaugh and Elsik (2000) assigned  $\pm 0.5$  Ma uncertainties to each of these ages. The upper Paleocene Lower Wilcox subunit, the most voluminous of the three subunits, which records the initial entry of Cenozoic sand into the basin (Galloway, 2001), is known in outcrop as the Indio Formation, Calvert Bluff Formation, Hooper Formation and Simsboro Formation, though the latter three names are restricted to northeast Texas (Thorkildsen and Price, 1991; Stoesser et al., 2005). The Middle Wilcox subunit, bounded above and below by transgressive shales, is sometimes included in the Lower Wilcox because it records mild regression in a period of overall waning sediment supply that followed the significant input of the Lower Wilcox and preceded the much larger Upper Wilcox (Galloway, 2005, 2008). The lower Eocene Upper Wilcox subunit, known as the Carrizo Formation in outcrop, is the result of a resurgence of sediment to the GOM following the volumetrically minor Middle Wilcox (Galloway, 2005). The regional-scale depositional architecture of the Wilcox Group shows changing depositional axes during the different pulses of sedimentation (Galloway, 1989). In broad terms the Lower and Middle Wilcox subunits were primarily deposited by the Rockdale Delta system in the Houston Embayment (Fisher and McGowen, 1967; Ayers and Lewis, 1985), while the Upper Wilcox subunit was primarily deposited by the Rosita Delta system in the Rio Grande Embayment to the south (Edwards, 1981) (Figure 1).

Deposition of the Wilcox group coincides with an active period of regional shortening and magmatism in the geologic history of western North America. Laramide tectonics were creating basement-cored uplands and adjacent basins in the region of the modern Rocky Mountains (Dickinson et al., 1988; Cather, 2004), while movement on the Sevier thrust belt farther west was waning, with the exception of the more northern sections of the belt (Miller et al., 1992). At the same time volcanism in the Cordilleran

arc was beginning to migrate inland toward the Laramide uplifts (Lipman, 1992; McDowell et al., 2001; Breyer et al., 2007; Befus et al., 2008), and previously active portions of the arc began to be uplifted (Miller et al., 1992). Deposition of the Wilcox Group preceded the voluminous mid-Tertiary ignimbrite flare-up of the southwestern U.S. and northern Mexico (McDowell and Keizer, 1977; Ferrari et al., 1999; Ferrari et al., 2002; Chapin et al., 2004), an event that buried older volcanic rocks in northern Mexico, making it difficult to determine their age and outcrop extent.

### **Previous Work**

Various possibilities have been proposed for the provenance of the Wilcox Group. The most commonly accepted interpretation, based primarily on the timing of uplifts and magmatic events, is that Wilcox sediment is derived from Laramide uplifts of the central and southern Rocky Mountains (Winker, 1982; Galloway, 2005), a concept that dates to the middle of the last century (Storm, 1945; Murray, 1955). In the same vein, Crabaugh (2001) correlated details of the uplift history of the late-stage Sevier thrust belt in the Green River Basin area of Wyoming to the depositional history of the Wilcox group, implying a northern Rockies provenance. Based on the presence of kyanite and staurolite in Wilcox strata of the northeast portion of the Texas Gulf Coast, Todd and Folk (1957) suggested that Wilcox sediments were most likely derived from the southern Appalachian mountains, though Brewton (1970) also examined the kyanite and staurolite content of Wilcox rocks and interpreted a southern Laramide source. Looking farther southwest along the coast, McCarley (1981) examined the ratio of garnet + epidote to kyanite + staurolite for several Eocene sands and determined that the Upper Wilcox could have been derived from southern Laramide uplifts. Based on zircon morphology, Callender and Folk (1958) concluded that the upper Wilcox did not have a volcanic source.

Figure 2. Map of sample area showing Upper Wilcox outcrop in cross-hatch pattern, Lower Wilcox outcrop in stipple pattern, Upper Wilcox deltas in down-to-the-right diagonal lines and Lower Wilcox deltas in down-to-the-left diagonal lines. Lower Wilcox sample locations are filled in squares and Upper Wilcox sample locations are filled in circles. Boxes around sample locations indicate a zircon sample. Empty circles with dots represent cities for geographic reference. County names are in all caps. Inset Texas State map shows regional geological features (i.e., the San Marcos Arch, the Houston Embayment, and the Rio Grande Embayment) and the sampling area as a dashed box. Wilcox outcrop from Stoesser et al. (2005). Upper and Lower Wilcox deltas after Edwards (1981).

## **METHODS**

Samples from the Upper and Lower Wilcox were collected from 18 outcrop localities and 5 cores (Figure 2). Geologic maps produced by the Bureau of Economic Geology, University of Texas at Austin (1976, 1983), supplemented by the stratigraphic column of Bee Bluff by Breyer (1997), were used to determine outcrop sampling locations. Cores were sampled from wells and depths previously studied by Fisher (1982), Loucks et al. (1984, 1986), and Dickerson et al. (1995). Sandstone point counts ( $n=350$  grains) were conducted on 40 thin sections using the Gazzi-Dickinson method (Ingersoll et al., 1984). Thin sections were impregnated with blue-dyed epoxy and stained for potassium feldspar and plagioclase using the techniques of Houghton (1980). Albitized and sericitized grains were counted as plagioclase. Raw point counts were recalculated using the parameters of Graham et al. (1976) (Table 1).

Geochronology samples were collected from both outcrop and core. Approximately 3-5 kg of material were collected from each sample locality. Core samples were collected from the sandiest parts of the core interval examined. A 1.5 m continuous section of core was sampled by cutting a 2.5 cm wide slice off of the back of the core. Prior to further processing, the pieces of core were washed and scrubbed with a wire brush to remove possible contamination from drilling mud. Samples were then crushed using a rock hammer and disc mill (Larsen and Poldervaart, 1957), and sorted by density using a Wilfley table and organic heavy liquids (bromoform ( $\rho=2.96 \text{ g/cm}^3$ ) and methylene iodide ( $\rho=3.32$ )). Prior to the heavy liquid mineral separation, a Frantz magnetic separator was used in freefall mode to remove metal shavings and strongly

Table 1. Point counting parameters.

Symbol	Definition
Qm	Monocrystalline quartz
Qpq	Polycrystalline quartz
Qc	Chert
Km	Microcline
Ko	Orthoclase
K	Potassium feldspar (= Km + Ko)
P	Plagioclase feldspar
Fu	Unknown feldspar
Lmf	Foliated quart-mica metamorphic grains
Lmp	Polygonal quartz-mica metamorphic grains
Lmqf	Quartzofeldspathic metamorphic grains
Lmu	Unknown metamorphic grains
Lss	Sedimentary lithic grains: siltstone, argillite, phosphatic grains
Lvf	Felsitic volcanic lithic grains
Lvl	Lathwork volcanic lithic grains
Lvm	Microlitic volcanic lithic grains
Lva	Altered volcanic lithic grains
Lvu	Unknown volcanic lithic grains
Lu	Unknown lithic grain
Qt	Total quartzose grains (= Qm + Qpc + Qc)
Qtc	Total quartzose grains excluding chert (= Qm + Qpc)
F	Total feldspar (= K + P + Fu)
Lm	Total metamorphic grains (= Lmf + Lmp + Lmqf + Lmu)
Lv	Total volcanic grains (= Lvf + Lvl + Lvm + Lva + Lvu)
Ls	Total sedimentary grains (= Lss)
L	Total unstable lithic grains (= Lm + Lv + Ls)
Qp	Total polycrystalline quartz (= Qpq + Qc)
Lt	Total lithic grains (= L + Qp)

magnetic minerals. Following the heavy liquid separation, samples were processed through a Frantz magnetic separator three times, once with all of the grains at 1.0 A, once with the non-magnetic fraction from the previous step at 1.8 A, and finally the magnetic fraction at 1.8 A to ensure that no non-magnetic grains had become entrained with the magnetic grains and improperly sorted. The mechanical parameters for each of these steps were set at 20° side slope and 20° front slope to minimize bias towards less paramagnetic age populations at the expense of increased discordance in the sample population (Sircombe and Stern, 2002). Zircon grains were visually picked under a binocular microscope, and then a random portion of the picked group was mounted on double stick tape in a 1mm x 1cm strip divided into 4 rows. Typically 250-350 grains were mounted per sample. Epoxy was poured around the grains to create a 1" diameter epoxy mount. The epoxy mount was ground using a 30  $\mu\text{m}$  grit grinding disc to expose the grains, and then polished using 1  $\mu\text{m}$  grit polishing paste. Cathodoluminescence (CL) images were produced for each grain to serve as a guide during ablation.

Zircon grains were analyzed on a GVI Isoprobe multicollector magnetic sector Laser Ablation-Inductively Coupled Plasma-Mass Spectrometer (LA-ICP-MS) with a Merchantek New Wave LUV213 sample introduction system, using a 213 nm Nd:YAG laser to ablate the grains. Faraday cups with  $10^{11} \Omega$  resistors were used to collect  $^{238}\text{U}$ ,  $^{207}\text{Pb}$ , and  $^{206}\text{Pb}$ , while a channeltron ion counter was used to collect  $^{204}\text{Pb}$  in isobaric interference with  $^{204}\text{Hg}$ . The laser was set at 52% power with a 30  $\mu\text{m}$  spot size and 10 Hz laser cycle, resulting in approximately 70-80  $\text{J}/\text{cm}^2$  of energy delivered to ablate the zircon grain during each analysis. U concentrations for each grain were determined based on an analysis carried out on NIST SRM 610 glass ( $^{238}\text{U}$  concentration  $\sim 461.5$  ppm) (Reed, 1992) at the beginning of each day. Prior to analysis, each grain was pre-ablated for 1-2 s with an expanded 410  $\mu\text{m}$  laser beam, delivering 2-3  $\text{J}/\text{cm}^2$  of energy, in

order to remove any material that may have accumulated on the grain surfaces while the mount was exposed during transfer to the sample introduction system. Each analysis consisted of 30 s data collection prior to ablation to measure background counts, otherwise known as an on peak zero, 10 s warm-up time for the laser and 20 s analysis time, followed by 20-30 s to flush the ablation chamber before analyzing the next grain. Every effort was made to ablate only the most recent magmatic growth of each grain since this will indicate its crystallization age and can be linked to a basement provenance. CL images were used to identify recycled cores and metamorphic rims on grains so that they could be avoided during isotopic analysis (Connelly, 2001; Corfu et al., 2003). Analyses of the in-house standard S97-19 were conducted after every 15 unknown grains to characterize mass fractionation and elemental (U/Pb) bias during the course of the day. S97-19 has been characterized by ID-TIMS at The University of Texas at Austin. In addition, the Plešovice (PL) zircon standard (Sláma et al., 2008) was analyzed to monitor system behavior. Typically 135-150 grains were analyzed per sample, so that even after rejecting some analyses due to high discordance or error there should be approximately 120 acceptable ages for each sample. This meets the criteria of Vermeesch (2004), so it is possible to be certain, at the 95% confidence level, of not missing a fraction of the population comprising at least 5% of the total population. While many detrital zircon studies typically have approximately 100 grains per sample (Dickinson and Gehrels, 2003, 2008a, b, 2009; Dickinson et al., 2009), Andersen (2005) warns that interpretations of the relative proportions of inputs from different source areas even when 120 grains are analyzed must be looked at with caution. In his study, Andersen (2005) used Monte Carlo simulations to compare the age spectra of samples of 120 grains drawn from a total population of 2000 grains to the age spectra of the total population, and found that the sample populations were not quantitatively similar to the total population.

Data were downloaded and reduced off-line using in-house Excel software to remove unacceptable data points for each analysis that may be the product of common Pb on the surface of the epoxy mount, ablating into another zone of the grain or ablating all the way through the grain. Depth-dependent U/Pb fractionation was also corrected at this step by using regression of the U/Pb data points to determine the initial U/Pb ratio at time zero (Kořler and Sylvester, 2003). A second step of data reduction was conducted to correct for mass fractionation, elemental bias, and initial Pb. An isobarically corrected  $^{206}\text{Pb}/^{204}\text{Pb}$  ratio was determined using the method of Gehrels et al. (2006), and then used to correct for common Pb using the Stacey and Kramers (1975) model for Pb evolution. Following established lab procedure, no uncertainty was applied to the common Pb correction. Work by the University of Texas at Austin LA-ICP-MS lab has found that for moderately radiogenic zircons, the uncertainty on the grain age is dominated by uncertainty on the U/Pb ratios, while uncertainty on the common Pb correction typically makes up less than 1% of the final age uncertainty (Housh, 2009, personal communication). Finally, mass fractionation and elemental bias factors determined on the standard were applied to the unknowns to determine the corrected, radiogenic  $^{206}\text{Pb}^*/^{238}\text{U}$  and  $^{207}\text{Pb}^*/^{206}\text{Pb}^*$  ratios and ages. The  $^{207}\text{Pb}^*/^{235}\text{U}$  ratio and age was determined using a  $^{238}\text{U}/^{235}\text{U}$  ratio of 137.88 (Faure and Mensing, 2005). Measured errors as well as the errors associated with mass fractionation and the elemental (U/Pb) bias determined on the standard S97-19 were propagated to yield the final errors on  $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ,  $^{206}\text{Pb}^*/^{238}\text{U}$ , and  $^{207}\text{Pb}^*/^{235}\text{U}$  for the unknown grains; measured errors alone are reported for  $^{206}\text{Pb}/^{204}\text{Pb}$ . The best ages for each grain were identified based on the  $^{206}\text{Pb}^*/^{238}\text{U}$  age for grains generally younger than 950 Ma and the  $^{207}\text{Pb}^*/^{206}\text{Pb}^*$  age for grains generally older than 950 Ma; however, the precise cutoff was picked individually

for each sample to avoid splitting up clusters of grain ages. Discordance for each analysis was determined using the following equation:

$$Discordance = \left( \frac{{}^{207}Pb^* / {}^{235}U \text{ age} - {}^{206}Pb^* / {}^{238}U \text{ age}}{({}^{207}Pb^* / {}^{235}U \text{ age} + {}^{206}Pb^* / {}^{238}U \text{ age})/2} \right) \quad (1.1)$$

Grains were filtered by discordance and error with the filter being set at -10% to 60% discordance for grains younger than 350 Ma, -10% to 30% discordance for grains 1000-350 Ma in age, and -5% to 10% discordance for grains older than 1000 Ma. Grains outside of those ranges or with  $1\sigma$  error exceeding 10% on the best age were excluded from further analysis. All plots and analysis were conducted using Isoplot 3.2 and 3.7 (Ludwig, 2003, 2008) and Excel worksheets designed by the University of Arizona Laserchron center (available online at [www.geo.arizona.edu/alch](http://www.geo.arizona.edu/alch)).

## RESULTS

### Sandstone Petrography

The samples in this study are very-well to moderately-well sorted, very fine- to medium-grained, subarkose, sublitharenite, litharenite, feldspathic litharenite, and lithic arkose (Folk, 1980) (Table 2). Framework grains include monocrystalline quartz; polycrystalline quartz; chert; plagioclase and albitized plagioclase; orthoclase; microcline; volcanic rock fragments, primarily highly altered felsitic and lathwork grains; metamorphic rock fragments; and sedimentary rock fragments. Large mica crystals, both biotite and muscovite, and zircons are the primary accessory minerals.

Huminite reflectance of shallow (200-565 m burial depth) Wilcox lignite and coal from northeast Texas suggests that it has not been buried deeper than its current location (Mukhopadhyay, 1989), whereas structural projections of more deeply buried strata from Leon County, Texas indicate that the Wilcox may have experienced up to 300 m of uplift (Galloway et al., 1994). McBride et al. (1991) suggested that as much as 762 m of Wilcox strata may have been eroded in Bastrop County, TX along the San Marcos Arch. If this uplift history is representative of the Wilcox in south Texas, then this would suggest that most up-dip Wilcox strata, not adjacent to the San Marcos Arch, have not experienced significant uplift. Despite the limited exposure to subsurface heating, outcrop samples show a significant diagenetic overprinting arising from processes within the meteoric regime of shallow burial, primarily dissolution of feldspar and lithic fragments. Approximately one-third of outcrop samples contain poikilotopic calcite cement; minor hematite or kaolinite cements are also common. In the case of calcite-cemented samples, intergranular volumes (IGV) in excess of 36% indicate an early

<sup>a</sup> The  $\chi^2$  test compares the actual values of a two or more sets of measurements to their expected values calculated based on the null hypothesis that each of the data sets is the same, and returns a probability (P) that the differences between the two data sets are random. If  $P < 0.05$ , then at a 95% confidence level the two data sets can be said to be different. If  $P \geq 0.05$ , then the two data sets are statistically the same. Tests where  $P \geq 0.05$  are marked by bold text.

<sup>b</sup> The Student's T-test compares the mean values for two sets of data, and returns a probability (P) that the differences between the two data sets are random. If  $P < 0.05$ , then at a 95% confidence level the two data sets can be said to be different. If  $P \geq 0.05$ , then the two data sets are statistically the same. Tests where  $P \geq 0.05$  are marked by bold text.

timing for complete calcite cementation (Paxton et al., 2002). Samples with IGVs in excess of 45%, even after correcting for obviously oversized patches of cement, most likely indicate fill of calcite cement into voids left by the dissolution of rock fragment and feldspar grains (Beard and Weyl, 1973; Pryor, 1973).

In comparison to outcrops samples, subsurface samples show less diagenetic alteration. All core samples but one (Winch St. 4-9948) contain quartz cement, typically 3%–5% but ranging up to 9%, with some samples also containing patchy kaolinite cement. Core samples also tend to display more variation in the content of rock fragments, especially in highly unstable volcanic rock fragments.

Wilcox samples plot mainly in the quartz recycled, transitional recycled and craton recycled fields in QmFLt space, and in the recycled orogenic and craton interior fields of the QtFL space (Dickinson and Suczek, 1979; Dickinson, 1985) (Figure 3). Although the compositional differences are not large,  $\chi^2$  tests of the QmFLt and QtFL values of the Upper and Lower Wilcox indicate that the differences are significant at the 95% confidence level (Folk, 1980) (Table 3). The Lower Wilcox is richer in lithic fragments, in particular chert and volcanic rock fragments, and feldspar, whereas the Upper Wilcox contains more sedimentary rock fragments. A possible cause of the differing proportions may relate primarily to the lack of volcanic rock fragments in the Upper Wilcox. While there are many differences between the Upper and Lower Wilcox samples, the percentage of metamorphic rock fragments and the ratio of plagioclase to total identifiable grains are fairly consistent.

Figure 4. Detrital zircon age probability distributions for all analyzed Wilcox samples. Numbers mark prominent age peaks. Horizontal bars labeled A–E indicate age populations described in text and table 5. N=number of samples, n= number of grains. (a) All grains from Wilcox Group. Subpopulations A1, A2, A3, and A4, of population A; B1, B2, and B3 of population B; and D1, D2, D3, D4, D5, and D6 of population D are indicated. Histogram bins equal 50 m.y. (b) Wilcox Grains younger than 350 Ma. Subpopulations E1, E2, E3, E4 and E5 of population E are indicated. Histogram bins equal 10 m.y.

Figure 5. Normalized age probability plots for all Wilcox Samples. Wilcox subunits are arranged in stratigraphic order. Samples within subunits are organized geographically from southwest at the bottom to northeast at the top.

Grain size is not a significant controlling factor in sandstone composition. Samples from core tend to have higher correlation coefficients ( $R^2$ ) between grain size and compositional parameters than outcrop samples (Table 4), but when the data for all samples are examined,  $R^2$  values are less than 0.3 for all recalculated ratios except LmLvLs%Ls. This indicates that while grain size has some control on composition, it typically does not account for more than 30% of the variation. The higher  $R^2$  values for core samples may be due to better compositional sorting in a high-energy delta-front to shallow-marine environment.

### **Detrital Zircon Geochronology**

U-Pb ages of detrital zircon grains from samples of the Wilcox Group range from 50 Ma to 3249 Ma (Figure 4, 5). Data tables and Concordia plots for each sample are available in Appendices C and D. Seven age populations can be discriminated based on the relative age probabilities (i.e., peaks and valleys) observed in the normalized age probability plot depicting all of the grains analyzed in this study (Table 5, Figure 4, Appendix F).

Population A represents a minor population composed of Archean and Paleoproterozoic grains (3250-1850 Ma). In contrast, the Paleoproterozoic to Mesoproterozoic (1819-1334 Ma) zircons of population B compose one of the two most prominent populations, making up 31% of the entire sample set, though there are wide variations in its prominence in individual samples, ranging from 12% to 58%. Population C is a relatively minor age population of Mesoproterozoic to Neoproterozoic (1326-937 Ma) grains. Population D is comprised of Neoproterozoic to Devonian (923-388 Ma) zircons that define a minor population composed of six low peaks. Mississippian to Paleocene (338-50 Ma) zircons of population E define a relatively major peak, made

Figure 6. Maps showing sample location and detrital zircon age probability distributions for each sample. Histogram bins equal 50 m.y., n=number of grains. Upper Wilcox outcrop in cross hatch pattern, Lower Wilcox outcrop in stipple pattern, Upper Wilcox deltas in down-to-the-right diagonal lines and Lower Wilcox deltas in down-to-the-left diagonal lines. Wilcox outcrop from Stoesser et al. (2005). Upper and Lower Wilcox deltas after Edwards (1981). (a) Lower Wilcox sample map. Lower Wilcox samples marked by squares. (b) Upper Wilcox Sample map. Upper Wilcox samples marked by circles.

Figure 7. Comparison of normalized age probability plots of the Upper and Lower Wilcox samples. Horizontal bars labeled A–E indicate age populations described in text and table 5. Upper Wilcox is in black, Lower Wilcox is in grey.  $N$ =number of samples,  $n$ =number of grains. Numbers mark prominent age probability peaks referenced in the text. (a) All grains in Upper and Lower Wilcox. Subpopulations A1, A2, A3, and A4, of population A; B1, B2, and B3 of population B; and D1, D2, D3, D4, D5, and D6 of population D are indicated. Plot is normalized so that the area under both curves is the same. (b) Upper and Lower Wilcox grains younger than 350 Ma. Subpopulations E1, E2, E3, E4 and E5 of population E are indicated. Plot is a rescaled version of figure 7A. It is not normalized to the number of grains younger than 350 Ma, but represents the fact that grains younger than 350 Ma make up a larger proportion of the Lower Wilcox than Upper Wilcox.

Table 6. (a) K-S test results for all grains in the Wilcox Group, Upper Wilcox, Lower Wilcox and individual samples. <sup>a</sup> (b) K-S test results for grains younger than 350 Ma in the Wilcox Group, Upper Wilcox, Lower Wilcox and individual samples. (c) K-S test results for grains older than 350 Ma in the Wilcox Group, Upper Wilcox, Lower Wilcox and individual samples.

up of a series of climbing peaks bounded by sharp lows, reaching its zenith at 99 Ma. Population E is present in all samples, and constitutes the second major peak of the Wilcox data set. Population E makes up 46% of the data set as a whole, but there is significant variability in its relative proportion within each sample (12%-70%).

Normalized age probability plots show that all of the samples are dominated by broad Mississippian to Eocene and Paleoproterozoic to Mesoproterozoic peaks (Figures 4, 5, 6 and 7), with all of the samples containing the same large scale populations though there are wide variations in the specific proportions of these populations between samples.

The Upper and Lower Wilcox have different U-Pb age distributions (Figure 7), as confirmed by the results of a Kolmogorov-Smirnov (K-S) statistical test to compare the two populations (Table 6a), conducted using Excel software provided by the University of Arizona Laserchron center (available online at [www.geo.arizona.edu/alc](http://www.geo.arizona.edu/alc)). In particular the Upper Wilcox has more of populations B, specifically B1 and B3, and C, while the Lower Wilcox contains more of population E. If grains younger than 350 Ma are examined more closely (Figure 7b), differences in populations E1 and E3 are apparent. Population E1 is distinct because it appears that in this age band the source areas of the Upper and Lower Wilcox are mutually exclusive (i.e., peaks in the Upper Wilcox age probability plot correspond to valleys in the Lower Wilcox age probability plot).

Statistically, the Lower Wilcox shows little similarity between samples, with only two of the ten possible sample combinations passing the K-S test (Table 6a) with  $P \geq 0.05$ . Burns 1, GM-W-051508-3, and GM-W-051608-4 all contain higher proportions of population E, but less of populations A and B, though only GM-W-051508-3 and GM-W-051608-4 are statistically similar ( $P=0.138$ ). Winch State 4 and GM-W-051408-1

contain higher proportions of populations A and B, but less of population E and are statistically similar ( $P = 0.065$ ). This later case is worth noting because Winch State 4 and GM-W-051408-1 are approximately 170 km apart, with Winch State 4 being deposited off of the depositional axis and GM-W-051408-1 being near one of the southern most deltas of the Lower Wilcox (Figure 6a). It is also interesting that Burns 1, in much closer proximity to GM-W-051408-1 than GM-W-051608-4 and taken from within the same delta that GM-W-051408-1 is near to (Figure 6a), is distinctly different from GM-W-051408-1 ( $P < 0.001$ ).

In contrast, the Upper Wilcox samples are much more statistically similar, with four out of ten possible sample combinations yielding P values greater than 0.05 (Table 6a). Bailey 1C and GM-C-051608-5 are statistically similar ( $P = 0.379$ ), while GM-C-051408-8 and Urban 1 barely fail the K-S test ( $P = 0.045$ ). Each of the samples contains a higher proportion of populations A and B to population E than the Lower Wilcox samples, except GM-C-051508-1 which is similar in composition to the Lower Wilcox average values.

If a geographic trend is defined as two adjacent (either along strike or dip) samples that are statistically similar then several trends can be noted. The first is that Lower Wilcox samples in the southwestern portion of the study area are more similar to Upper Wilcox samples in the same area than is the case in the northeastern portion of the study area. Bailey 1C and Winch State 4, GM-W-051508-3 and GM-C-051508-1, GM-C-051608-5 and Winch State 4, and GM-C-051508-1 and GM-W-051608-4 are all Lower Wilcox-Upper Wilcox sample pairs from the southwestern portion of the study area that pass the K-S test, while only GM-W-051408-1 and Urban 1 and Burns 1 and GM-C-051508-1 are sample pairs from the northeastern portion of the study area that pass the test. Second, as previously noted, the Upper Wilcox is fairly uniform across its

geographic extent. Most Upper Wilcox samples, with the exception of GM-C-051508-1, have higher proportions of populations A and B to population E than is seen in the Lower Wilcox. Finally, in the Lower Wilcox, where GM-C-051508-1 and GM-C-051608-5 are the only adjacent samples that are statistically similar, there appears to be no coherent regional trend, with samples that differ greatly in age distribution being adjacent.

There are two important considerations when interpreting these results. The first is that interpretations of the relative proportions of different age populations may not be valid with the sample sizes used in this study (Andersen, 2005). With this in mind it is worth noting that all of the major age populations (i.e., B1, B3, C and E) are represented in each sample, though not each of the subcomponents of population E are present in every sample. This is typically the case in samples where population E makes up less than 30% of the sample population, except in the case of sample GM-C-051608-5. The second consideration is that the precise stratigraphic and temporal relationship between each of the samples is not known. Consequently it is difficult to determine if differences in the relative proportions of the age populations are the result of sampling deposits of multiple contemporaneous rivers systems draining different areas, or if there was a single river system and changes in relative proportions reflect changes in the drainage of that river system. It is unlikely that all of the samples are stratigraphically correlative, but this in itself does not preclude either of the options above. The depositional history of the Wilcox (Galloway, 2001) supports the presence of the multiple river systems, but this does not preclude an evolution of the drainage through time within in each subunit.

Two additional K-S tests were conducted to compare only the grains younger than 350 Ma or older than 350 Ma between the Upper and Lower Wilcox, as well as between the individual samples (Tables 6b and 6c). The results of these tests show that for the Upper and Lower Wilcox subunits and for most individual samples the populations of

grains younger than 350 Ma and older than 350 Ma are statistically similar. This suggests that the principal difference between the two subunits lies in the relative proportion of grains younger than 350 Ma and those older than 350 Ma. As will be shown later the grains younger than 350 Ma of population E likely come from related sources areas, but the same is not true for the grains older than 350 Ma grains of populations A, B, C and D. Regardless, there is a mild correlation ( $R^2=0.45$ ) between the proportions of populations A and B, the two largest older than 350 Ma, if the data from the Urban-1 well is excluded on the basis of small sample size (there are only 45 acceptable grain ages for this sample).

The youngest grains in both the Upper and Lower Wilcox nearly approximate the age of deposition. The average age of the three youngest grains in the Lower Wilcox is 63 Ma while Lower Wilcox deposition ended at 57.5 Ma (Crabaugh, 2001). The time difference is even less in the case of the Upper Wilcox, where the average age of the three youngest grain is 51 Ma and deposition ceased at 49 Ma (Crabaugh, 2001).

## **DISCUSSION**

### **Sandstone Petrography**

The lithic fragments present in Wilcox sandstone samples suggest a variety of source rock types. Siltstone and sandstone lithic fragments, together with quartz grains with recycled overgrowths, indicate derivation from clastic sedimentary rocks, whereas chert grains could indicate either a carbonate or deepwater marine source (Mack, 1981). The presence of rip-up clasts similar in composition to the samples in the Upper Wilcox indicates some amount of local recycling of sediment. Volcanic lithic fragments are present in both the Lower Wilcox and Upper Wilcox subunits, indicating volcanogenic

input into both subunits. Metamorphic fragments, typically non-foliated and only containing small mica crystals, as well as polycrystalline quartz fragments that do not show signs of high-grade metamorphism (i.e., small crystals with undulose crystal boundaries and undulatory extinction) are indicators of low-grade metamorphic sources (Young, 1976; Garzanti and Vezzoli, 2003), whereas large mica crystals could be remnants of schistose metamorphic rock fragments that did not survive transport (Cameron and Blatt, 1971). The Gazzi-Dickinson point counting method does not count plutonic rock fragments due to their large crystal size (Ingersoll et al., 1984), but a tally was kept of framework grains that appear to be part of a plutonic rock fragment during point counting. The number of plutonic rock fragments is very low, typically only one or two per sample, but this is not unexpected given the grain size of the samples and the transport distances to potential plutonic sources.

As stated previously,  $\chi^2$  tests show that the Upper and Lower Wilcox are statistically different (Tables 3a and 3b). The Lower Wilcox contains more volcanic rock fragments, suggesting either enhanced input or greater proximity to volcanic provinces in northern Mexico and the Cordilleran magmatic arc. The chert to total quartz and chert to total lithics ratios are not statistically similar between the Upper and Lower Wilcox subunits (Table 3c). If the ratios were the same for both subunits this would suggest that most of the chert was derived during transport from local sources available to both units, such as Cretaceous limestone units covering much of central Texas (Galloway, 2008). That they are not implies that most of the chert was derived from external uplifts. This is supported by the lack of carbonate rock fragments in either subunit, which are unlikely to survive the long transport distances from external uplifts (Mack, 1984). The statistically significant greater proportion of chert in the Lower Wilcox implies that it drew more sediment from distant carbonate-rich sources (Mack, 1981), which could point to

derivation from sources in northern Mexico (McBride et al., 1974; McKee et al., 1990). This suggests that most of the chert was derived from external uplifts tapped only by the Lower Wilcox, instead of continuously exposed local sources, thus explaining why no carbonate rock fragments were recorded in either subunit. Metamorphic rock fragments are consistent with derivation from the southern Laramide province (McCarley, 1981). The percentage of metamorphic rock fragments is statistically consistent between the two units indicating relatively similar inputs, but as in the case of the other rock fragments, the raw counts vary greatly, suggesting that the source areas were not of uniform composition.

The compositional differences between the Upper and Lower Wilcox suggest contrasting source areas. The higher proportion of volcanic rock fragments and chert grains in the Lower Wilcox suggest derivation from volcanic and carbonate-rich sources, possibly in the Cordilleran arc or northern Mexico. The Upper Wilcox is more quartzose, and contains a higher proportion of sedimentary and metamorphic rock fragments suggesting derivation from basement and clastic sedimentary rich sources, pointing towards Laramide basement uplifts.

Figure 8. Map of basement rock ages of North America. Basement provinces and ages modified from Dickinson and Gehrels (2009), Sevier thrust belt modified from DeCelles (2004), central and southern Laramide uplifts modified from Dickinson and Gehrels (2008a), and 1.5-1.35 Ga plutons from Hoffman (1988).

## **Detrital Zircon Geochronology**

Most of the U-Pb ages for detrital zircon grains can be attributed to basement sources in the central and southern Laramide uplifts and the Cordilleran magmatic arc of western North America, though some grains may have come from recycling of sedimentary rocks.

### ***Major Sources***

Population B (1819-1334 Ma) is most likely derived from the Laramide basement uplifts of the central and southern Rocky Mountains (Figure 8). Population B1 coincides in age with the 1800-1650 Ma basement rocks of the Yavapai and Mazatzal orogenies of New Mexico, Arizona and Colorado, which form the core of most of the Laramide uplifts (Condie, 1982; Grambling et al., 1988; Pedrick et al., 1998; Karlstrom et al., 2004). The distribution of grain ages (Figure 4) suggest that most grains were derived from the younger, more southerly Mazatzal orogenic belt (Karlstrom et al., 2004) instead of the older, northern Yavapai belt. Alternative sources for this age range include the Mojave basement (Barth et al., 2009) exposed by basement uplifts in southern California and western Arizona (Miller et al., 1992), though much of the sediment from these uplifts could have been trapped by the adjacent basins. Basement of this age is also exposed in Sonora, Mexico (Andersen and Silver, 1981), which would be difficult to distinguish from Yavapai-Mazatzal basement farther north. Population B3 is from the dominantly 1500-1350 Ma granitic intrusions in the southwestern U.S. (Anderson, 1983; Hoffman, 1988; Hoffman, 1989; Karlstrom et al., 1997; Karlstrom et al., 2004) and Sonora (Andersen and Silver, 1981). Work on the “zircon fertility” of various Precambrian plutons of North America suggest that the amount of sediment derived from ~1400 Ma plutons in the southwestern U.S. is most likely less than what is represented by their

proportion of the zircon age spectrum (Dickinson, 2008). One complicating factor is that grains of B1 and B3 age are found in Mesoproterozoic to Triassic strata of the western U.S. and northern Mexico (Gehrels and Dickinson, 1995; Gehrels et al., 1995; Gehrels and Stewart, 1998; Stewart et al., 2001), though these would most likely have been eroded off uplands that subsequently exposed basement. This does not change the provenance interpretation, though it does imply a different source rock type. Population B2 is more challenging to explain because the only documented basement rocks of this age are in the 1577-1576 Ma Laclede augen gneiss of the Priest River Complex in British Columbia (Doughty et al., 1998). Detrital zircons of this age, believed to have been ultimately derived from the Gawler craton of Australia, are found in strata ranging from Alaska's Alexander terrane to the Marathon basin of west Texas (Stewart et al., 2001; Gleason et al., 2007). In this case, population B2 represents recycling of sedimentary sources into the Wilcox Group.

Population E represents the Cordilleran magmatic arc and its predecessors. Continental magmatism in the Cordilleran arc began around 245 Ma in the Mojave Desert region (Barth and Wooden, 2006; Dickinson and Gehrels, 2009). Following its initiation in the early Triassic, arc magmatism was very continuous and widespread for most of its history (Stewart et al., 1986; Busby-Spera, 1988; McKee et al., 1990; Cowan and Bruhn, 1992; Miller et al., 1992; Saleeby and Busby-Spera, 1992; Gehrels and Stewart, 1998; Dickinson and Lawton, 2001; Kimbrough et al., 2001; Ortega-Rivera, 2003; Wetmore et al., 2003; Busby, 2004; Lawton et al., 2009). Because of this, it would be difficult to assign specific source areas for arc grains based on age alone, though it is interesting to note that the Wilcox age probability curve reaches its peak around 99 Ma (Figure 4b), a time at which the Peninsular Range Batholith and Sierra Nevada Batholith were peaking in magmatic output (Miller et al., 1992; Kimbrough et al., 2001; Ortega-

Rivera, 2003). Grains in population E1 older than 245 Ma could have come from several sources: 1) Mississippian ash-flow tuffs of the Tesnus Formation in the Marathon Basin (Imoto and McBride, 1990), 2) the 334 Ma El Aserradero Rhyolite of the Sierra Madre near Ciudad Victoria, Mexico (Stewart et al., 1999), 3) the 331 and 285 Ma plutons and 303 and 268 Ma volcanics of the Las Delicias Arc, Coahuila Terrane (Lopez, 1997; Stewart et al., 1999; Lopez et al., 2001), 4) the 284-232 Ma East Mexico Arc (Torres et al., 1999), or 5) the Lovelock and Luning assemblages of Nevada, where grains as old as 281 Ma have been reported (Manuszak et al., 2000). These suggest sources from northern and eastern Mexico as well as central Nevada, both of which are source regions corroborated by other age peaks. Near the end of the Cretaceous, arc magmatism for most of the western U.S. began to wane, while simultaneously migrating landward in northern Mexico and the western U.S. (Lipman, 1992). Grains younger than 80 Ma are most likely from igneous activity in northern Mexico (McDowell and Clabaugh, 1984; McDowell and Mauger, 1994), southern New Mexico (Chapin et al., 2004) and west Texas (Breyer et al., 2007; Befus et al., 2008), though activity in northern Mexico and southern New Mexico also overlaps temporally with activity farther west in the arc (McDowell et al., 2001; Chapin et al., 2004). Although there was voluminous magmatic activity in the Boulder, Pioneer and Idaho batholiths of Idaho and Montana after 100 Ma (Miller et al., 1992), the paucity of Archean age grains (Figure 4a) makes them unlikely sources because there is Archean basement in Sevier and Laramide uplifts in the same region (Ross et al., 1955; Armstrong and Hills, 1967; Doughty et al., 1998; Chamberlain et al., 2003).

### ***Minor Sources***

3250-2620 Ma grains could have come directly from the Archean Wyoming province (Chamberlain et al., 2003), but this is not supported by current theories (e.g. Dickinson et al., 1988; Lawton, 2008) of the internal drainage structure of the northern Laramide uplifts and ponded basins. Grains of the same wide range of ages as Population A are common in arc and coastal terranes of California and Oregon (i.e. the northern Sierra Terrane, Eastern Klamath Terrane, Yreka Terrane, Black Rock Terrane and Shoo Fly Complex) (Darby et al., 2000; Gehrels et al., 2000a; Gehrels and Miller, 2000; Harding et al., 2000; Spurlin et al., 2000; Wallin et al., 2000) which were accreted to the western Cordilleran margin by Late Jurassic time (Saleeby and Busby-Spera, 1992), as well as farther inland in the Roberts Mountain allochthon, Antler foreland basin, Golconda allochthon, and Triassic assemblages of western Nevada (Gehrels and Dickinson, 2000; Gehrels et al., 2000b; Manuszak et al., 2000; Riley et al., 2000). The paucity of 338-358 Ma grains in the Wilcox samples suggests against the Golconda allochthon being one of the sources. While this may seem overly complex, the data point toward two broad source areas: arc terranes of northern California/Oregon and allochthons and parautochthons of western Nevada. The Archean and Paleoproterozoic grains of these samples were probably derived from the same ultimate source, the Paleozoic Peace River Arch (Gehrels et al., 2000a), and have been recycled from older strata into younger ones in these arc terranes, allochthons and parautochthons. Some older basement maps (e.g., Hoffman, (1988)) indicate that the Mojave basement could have been the source of 2300-2100 Ma grains. More recent studies (Barth et al., 2000; Barth et al., 2001; Barth et al., 2009) indicate that the primary magmatic age of Mojave basement is 1800-1630 Ma, with 2300-2100 Ma ages existing only as cores. The negative

Figure 9. Comparison of normalized age probability plots of the Wilcox Group samples and Dickinson and Gehrels (2008a) samples. Wilcox Group is in black, Dickinson and Gehrels (2008a) is in grey. N=number of samples, n=number of grains. Numbers mark prominent age probability peaks referenced in the text. (a) All grains in Wilcox Group and Dickinson and Gehrels (2008a). Plot is normalized so that the area under both curves is the same. (b) Wilcox Group and Dickinson and Gehrels (2008a) grains younger than 350 Ma. Plot is a rescaled version of figure 9A. Plot is not normalized to the number of grains younger than 350 Ma, but represents the fact that grains younger than 350 Ma make up a larger proportion of the Wilcox Group than the sediments of the Cordilleran foreland basin.

correlation between populations A and E ( $R^2=.64$ ) suggest that the arc terranes of California and Oregon may not be as large of contributor. If the opposite were the case then a positive correlations would be expected due to proximity to the Cordilleran arc. This implies that much of population A may have originated from the allochthons of Nevada. Alternatively, the arc terranes in California and Oregon could have been sources if little arc material originated from that far north.

There are numerous possible sources for the Grenville-age grains of population C, though due to the high zircon content of Grenville plutons (Dickinson, 2008), the total sediment volume that these sources yield is almost certainly overestimated if based on zircon populations alone. Grenville-age grains are common in Cordilleran foreland basin sediments (Figure 9a) (Dickinson and Gehrels, 2008a) where they are believed to be derived from Jurassic and Permian eolianites (Dickinson and Gehrels, 2003, 2009) uplifted by the Sevier thrust belt. A statistical (K-S test,  $P<0.001$ ) comparison of grains indicate that the Cordilleran foreland basin, and therefore the Sevier thrust belt, were not the likeliest sources of the Wilcox Group (Dickinson and Gehrels, 2008a). This is supported by differences in the character of the peaks at 412 Ma (D6) and 600 Ma (D4) between the Wilcox Group and Cordilleran foreland basin (Dickinson and Gehrels, 2008a) (Figure 9a), which Dickinson and Gehrels (2009) attribute to Taconic plutons in the case of the former and either Pan-African sources or pre-Iapetan rift plutons related to the break up of Rodinia in the case of the later. The Llano uplift of central Texas contains modern exposure of Grenville age basement in close proximity to the Texas Gulf Coast (Mosher, 1998). Though it is uncertain whether the Llano uplift was covered by Cretaceous carbonates during the Paleocene and Eocene (Ewing, 2005), it is not a likely source for the Wilcox Group because it differs significantly in its kyanite, staurolite, and green hornblende content (Todd and Folk, 1957). The southern and

central Appalachian Mountains are also an unlikely source because the major pulses of granitic intrusions are younger than the ages observed in the Wilcox samples (Aleinikoff et al., 2000; Eriksson et al., 2003). Other potential sources of Grenville-age grains include basement rocks of the Franklin Mountains in west Texas (Mosher, 1998), 1100 Ma intrusions in Sonora (Andersen and Silver, 1981), and the 1090 Ma Pikes Peak Batholith (Anderson, 1983; Smith et al., 1999), though none of these ages match precisely the age peaks in Population C. Therefore, the most likely source for population C is basement in Mexico (Dickinson and Lawton, 2001), particularly 1150-1230 Ma basement in the Oaxaquia microcontinent of eastern Mexico (Ortega-Gutierrez et al., 1995; Lawlor et al., 1999; Lopez et al., 2001; Cameron et al., 2004) and 1170-1220 Ma basement in the Coahuila terrane (Lopez, 1997) which seem to be good matches for the primary 1189 Ma and lesser 1118 Ma age peaks in the Wilcox samples (Figure 4).

Population D most likely represents a mix of sources from the arc terranes of California and Oregon with the sedimentary rocks of the western U.S. and northern Mexico. The ultimate source of D1 is enigmatic, though grains of this age are present in minor amounts in Jurassic eolianites of the southwestern U.S. (Dickinson and Gehrels, 2009) and the Haymond Formation of the Marathon Basin (Gleason et al., 2007). While this does not necessarily mean that sediments derived from the Marathon Basin or Jurassic eolianites were incorporated in the Wilcox, it does indicate that grains of that age were present in North America, even if the source is unknown. D2 grains are most likely from Pan-African terranes associated with the Appalachian orogen or from plutons related to the Neoproterozoic breakup of Rodinia, and are seen in Mesoproterozoic strata in Sonora and miogeoclinal strata of the western U.S., as well as being present as a minor population in the Marathon Basin (Stewart et al., 2001; Dickinson and Gehrels, 2003; Cather et al., 2006; Gleason et al., 2007). The Roberts Mountain Allochthon is the likely

proximal source for population D3, though the ultimate source is likely either Pan-African grains of the Appalachian orogen or an unknown source in the southwest U.S. (Gehrels et al., 2000a; Dickinson and Gehrels, 2003). There are several possible sources for population D4 which are difficult to differentiate: 1) Jurassic eolianites (Dickinson and Gehrels, 2003), 2) igneous rocks of the Trinity terrane (Gehrels et al., 2000a), 3) Cambrian-Ordovician intrusive rocks of the New Mexico aulacogen (McMillan and McLemore, 2004), or 4) gabbros of the Oklahoma aulacogen that have returned U-Pb zircon ages around 577 Ma (Keller and Baldrige, 1995; Hogan and Gilbert, 1998). The last option was probably not a significant source due to the lack of evidence of mafic material in the sandstone point counts. The most likely of these four sources, based primarily on which sources are deemed to be significant to the Wilcox, are the Trinity terrane and New Mexico aulacogen. The Oklahoma aulacogen is a much better age and source match for Population D5 (Keller and Baldrige, 1995; Hogan and Gilbert, 1997; Hogan and Gilbert, 1998). The Oklahoma aulacogen need not provide sediment directly to the Wilcox as it was uplifted as part of the Pennsylvanian-Permian Ancestral Rocky Mountains and zircons of this age are very prominent in Triassic strata from Texas to Utah (Dickinson and Gehrels, 2008b). Population D6 matches well, and is most likely derived from, igneous rocks of the northern California/Oregon arc terranes (Gehrels et al., 2000a), though detrital zircon grains (369-457 Ma) found in volcanic and metamorphic boulders in the Haymond Formation of the Marathon Basin (Denison et al., 1969) which Gleason et al. (2007) attribute to unknown sources in Mexico are also a good match. Taconic sources are unlikely as there are major differences in the Taconic ages peaks between the Wilcox and the most likely source of Taconic grains, the Sevier thrust belt (Dickinson and Gehrels, 2008b), is not a likely source for much of the sediment delivered to the Wilcox Group.

## ***Summary***

The detrital zircon age spectra suggest that the Wilcox Group had a large drainage area, with the primary sources being central and southern Laramide uplifts and the Cordilleran magmatic arc of western North America. The lack of a prominent Grenville age peak (Figure 9a) precludes the Cordilleran foreland basin or the Sevier thrust belt from being major contributors, and the distribution of ages for population C suggests that the Grenville grains were probably derived from basement in Mexico. Considering the regional tectonic history prior to and during Wilcox deposition, these source areas are reasonable because: 1) the Rocky Mountains were experiencing shortening-related uplift (Dickinson et al., 1988; Cather, 2004) but still had drainage outlets to the south (Lawton, 2008), 2) the Cordilleran arc was undergoing uplift as magma production began to wane (Miller et al., 1992; Ortega-Rivera, 2003), and 3) magmatism was migrating cratonward into Mexico and the southwestern U.S. (Lipman, 1992; McDowell et al., 2001; Chapin et al., 2004). Sediment from the Sevier thrust belt and northern Rocky Mountain province would have been trapped in the ponded and perimeter basins associated with the northern Laramide uplifts (Dickinson et al., 1988; Lawton, 2008), so its absence is not unexpected.

Arc sources in particular represent a wide geographic area, with likely sources as far north as the arc terranes and allochthons of California, Oregon and Nevada, and as far south as the East Mexico Arc of southern and central Mexico. Comparisons of the Wilcox data to the Cordilleran foreland basin data of Dickinson and Gehrels (2008a) and the Difunta Group data of Lawton et al. (2009) indicate that in the grain population younger than 350 Ma there are not any peaks present in either of the other two data sets that are not also present in the Wilcox Group (Figures 9b and 10). In a rough sense, this correlation suggests that the Wilcox sediment was drawn from the same arc sources

Figure 10. Comparison of normalized age probability plots of the Wilcox Group samples and Lawton et al. (2009) samples younger than 350 Ma. Wilcox Group is in black, Lawton et al. (2009) is in grey. N=number of samples, n=number of grains. Numbers mark prominent age probability peaks referenced in the text. Plot is a rescaled version of a normalized age probability plot of both samples. Plot is not normalized to the number of grains younger than 350 Ma, but represents the fact that grains younger than 350 Ma make up a smaller proportion of the Wilcox Group than the sediments of the Difunta Group.

that fed the other two, with the Cordilleran foreland basin data approximating the zircon signature of the northern arc sources and the Difunta group the zircon signature of the southern arc sources. This interpretation is substantiated by age peaks at 150-114 Ma, present in the Wilcox Group and Difunta Group only, and 227 Ma, present in the Wilcox Group and Cordilleran foreland basin only. While the provenance of the 227 Ma peak is hard to pin down because it is found in strata of the Luning, Lovelock and Pine Nut assemblages emplaced during the Sonoman Orogeny (Manuszak et al., 2000) as well as in granites and strata in Sonora (Gehrels and Stewart, 1998), the 150-114 Ma peak most likely corresponds to activity in the Peninsular Range Batholith and Alisitos Arc of southern California and the Baja Peninsula (Dickinson and Lawton, 2001; Kimbrough et al., 2001; Ortega-Rivera, 2003; Wetmore et al., 2003; Lawton et al., 2009) which would have been blocked from delivering sediment to the Cordilleran foreland basin by the Mogollon highlands (Cumella, 1983; Dickinson and Gehrels, 2008a). This, along with some striking similarities between the age probability curves of the Wilcox and the Cordilleran foreland basin, even though the latter did not provide sediment directly to the former, is a good indicator that the Wilcox depositional system incorporated sediment from both the northern and southern sections of the arc. A peak at 200 Ma in the Wilcox Group that is absent in both the Difunta Group and the Cordilleran foreland basin (Dickinson and Gehrels, 2008a; Lawton et al., 2009) (Figures 9b and 10) indicates that it also drew sediment from arc sources not available to the other two.

The cause of the distinct differences in the age signatures of population E1 in the Upper and Lower Wilcox from 340 Ma to 220 Ma is hard to explain (Figure 7b). The Upper Wilcox contains grains that correspond in age to the East Mexico Arc (284-232 Ma) (Torres et al., 1999), with a lesser peak at 327 Ma that could correspond to the Aserradero Rhyolite or the Las Delicias Arc (Lopez, 1997; Stewart et al., 1999; Lopez et

al., 2001). The Lower Wilcox contains age peaks at 298-272 Ma, 253 Ma, 313 Ma and 338 Ma. These ages overlap with known ages for the East Mexico Arc, as well as volcanic and plutonic activity seen further north in Mexico (Imoto and McBride, 1990; Lopez, 1997; Stewart et al., 1999; Torres et al., 1999; Lopez et al., 2001). That the possible source areas for the two subunits seem to geographically overlap yet yield age signatures that are distinctly different highlights the difficulty in precisely identifying source areas with detrital zircon data, and opens the possibility that an as yet unknown source contributed sediment to the Wilcox Group. In this case all that can be said for sure is that two distinct source areas preferentially contributed 340 Ma to 220 Ma sediment to the Upper and Lower Wilcox subunits, though it is difficult to resolve the details.

Figure 7b and table 5 show that the Upper and Lower Wilcox subunits received different enough proportions of sediment from the various source areas to be statistically distinct (Table 6). If the specific source areas mentioned above are applied to these differences, then the Lower Wilcox is enriched in sediment from the Cordilleran arc and northern Mexican volcanics, while the Upper Wilcox is enriched in sediment from Laramide basement uplifts of the central and southern Rockies and Mexico, volcanic arc terranes of western North America and the Roberts Mountain Allochthon. None of these source areas is absent from either the Upper or Lower Wilcox, so any changes in the source area were not large enough to exclude one of them. While the age spectra for populations A, B1, B2, C and D are visually similar between the two subunits, there are some differences in the age spectra for populations E and B3 (Figure 7b). As discussed in the previous paragraph, the Cordilleran arc and northern Mexican volcanics are the most likely sources for population E to both the Upper and Lower Wilcox, even though the temporal evolution of this source area is hard to resolve. Likewise, both the Lower Wilcox (1393 Ma) and Upper Wilcox (1456 Ma) B3 peaks (Figure 7a) correspond in age

to granitic intrusions in western North America (Andersen and Silver, 1981; Anderson, 1983; Hoffman, 1988; Hoffman, 1989; Karlstrom et al., 1997; Karlstrom et al., 2004), even though the difference in age peaks suggests derivation from different parts of this source. This indicates that even though there were some differences in how each sub unit received sediment corresponding to those age populations, the source regions they represent for each subunit are the same.

There is a contrast between the source areas suggested by the sandstone modal composition and the detrital zircons. While the Upper and Lower Wilcox plot primarily in the quartzose recycled and orogenic recycled fields on QmFLt and QtFL diagrams (Figure 3), the detrital zircon data suggest that there was a significant volcanic arc and basement input. The statistically significant increase in the plagioclase to total identifiable feldspar ratios between outcrop and core samples (student's t-test,  $P < 0.001$ ), implying albitization and destruction of potassium feldspar, suggest that some of the difference between the sources suggested by petrography and geochronology may be due to diagenetic effects. Still the core samples are still far more quartzose than the detrital zircon geochronology suggest. A significant body of literature (e.g., Potter, 1978; Suttner et al., 1981; Mack, 1984; Johnsson et al., 1988; Johnsson, 1990; Johnsson and Meade, 1990; Avigad et al., 2005) suggests this disparity could be the result of humid climate weathering during transport along the low relief coastal plane of the northern Gulf of Mexico, especially concerning the preferential loss of volcanic rock fragments (Smyth et al., 2008).

There has been some suggestion that sedimentation in the southwestern portion of the Lower Wilcox was the result of long-shore drift of sediment originating in the deltas to the northeast (Fisher and McGowen, 1967; Dickerson et al., 1995). The detrital zircon data shows however that Lower Wilcox sediment in the southwestern portion of the study

area is more related to the overlying Upper Wilcox sediment than it is to the Lower Wilcox sediment in the northeastern portion of the study area. This suggests that river systems of the Upper Wilcox in far south Texas were already active during deposition of the Lower Wilcox. The data from this study do not support the idea of significant long-shore drift derived strand plain sedimentation in the Lower Wilcox, though they do not definitively refute it either.

## **CONCLUSIONS**

The broad, continent-scale derivation of the Wilcox Group is likely to be from three principal source areas: 1) central and southern Laramide uplifts south of the Archean-Proterozoic suture at the Wyoming Shear Zone (Condie, 1982), as represented in the consensus from previous studies, 2) the Cordilleran arc as Miller et al. (1992) suggested, and 3) the volcanics of northern Mexico. The Cordilleran foreland basin and the Sevier thrust belt were not major sources. Both the major grain populations and the detrital zircon data support a change in provenance from a source richer in volcanic rock fragments and young zircons in the Lower Wilcox, to a source richer in basement-derived zircons in the Upper Wilcox. Tentatively, humid climate weathering is implicated in the failure of major grain modal composition to more fully reveal the complex sources indicated by the zircons.

## **Appendix G : Review of Zircon Characteristics and Literature**

In recent years U-Pb detrital zircon geochronology by Laser Ablation-Inductively Coupled Plasma-Mass Spectrometry (LA-ICP-MS) has moved to the forefront of sedimentary provenance studies due to its ability to discriminate between potential sedimentary sources (e.g. Fedo et al., 2003). Zircons have long been used in geochronological studies because they typically contain 10-1000 ppm of U (Speer, 1980), but little initial Pb due to the size of their cation sites (Larsen et al., 1952), making them ideal for U-Pb geochronology. Zircons are suitable for sedimentary provenance studies because of their resistance to abrasion during transport (Larsen et al., 1952), chemical alteration during weathering and diagenesis (Milliken and Mack, 1990; Morton and Hallsworth, 1994), and minimal Pb-loss even at low-grade metamorphic temperatures unless they are metamict from age or high U content (Cherniak et al., 1991; Cherniak and Watson, 2001; Cherniak and Watson, 2003). Because of their high density ( $\rho=4.66 \text{ g/cm}^3$  (Finch et al., 2001)) compared to the major constituents of sedimentary rocks, quartz ( $\rho=2.65 \text{ g/cm}^3$ ) and feldspar ( $\rho=2.55\text{-}2.76 \text{ g/cm}^3$ ) (Nesse, 2000), zircons are included in the heavy mineral separate when the individual grains of a disaggregated sedimentary rock are separated using density sorting techniques, such as the Wilfley table or heavy organic liquids. The density difference also means that zircons are hydrodynamically equivalent to quartz grains one  $\phi$  size larger (Komar et al., 2007). This is an important relationship to consider when sampling, as a very fine sandstone is likely to produce zircons that are too small to analyze with a LA-ICP-MS. Pure zircons are diamagnetic (Lewis and Senftle, 1966; see Sircombe and Stern (2002) for further discussion) and can easily be separated from the majority of the heavy minerals using a Frantz magnetic separator. Since there is a positive correlation between Pb-loss/discordance, U content and magnetic susceptibility (Silver, 1963), magnetic separation can also be used to remove discordant zircons, leaving only those that are likely to return acceptable data.

Improvements in LA-ICP-MS technology have reduced the cost and time involved in acquiring zircon age data of sufficient accuracy for provenance studies. This has resulted in the analysis of more grains from each sample, allowing quantitative studies, those which attempt to determine the proportions of different age populations, to be conducted instead of qualitative studies, which can only determine which ages are present (Fedo et al., 2003).

The detrital zircon technique has proved capable in examining a wide variety of geological problems, from confirming the long-distance drainage of ancient river systems (Rainbird et al., 1992) to determining whether an off-shore arc terrane developed near or far from the craton to which it is now accreted (Gehrels et al., 2000a). Such determinations cannot be made using sandstone petrography alone. However, combining detrital zircon geochronology data with sandstone petrography data makes provenance interpretations more robust by considering not only the age spectra of sediment sources, but also rock type and tectonic setting (e.g., Dickinson and Suczek, 1979; Dickinson, 1985). Comparison of sandstone modal compositions to detrital zircon age spectra can also help identify chemically mature, first-cycle quartz arenites that are a result of humid climate weathering (Avigad et al., 2005). Further, sandstone petrography can identify any potential sources (e.g., mafic source rocks) that may not produce zircons due to their bulk chemistry, and therefore may be overlooked in the age spectra (Fedo et al., 2003).

The resiliency of zircons to abrasion during sedimentary transport (Morton et al., 1996) and to chemical weathering and diagenesis (Milliken and Mack, 1990; Morton and Hallsworth, 1994) makes them suitable for identifying source areas, but is also a complicating factor in that they are subject to multiple stages of recycling. This process is well observed in the studies of Dickinson and Gehrels (2003, 2008a, 2009) where zircons derived from Grenville and Appalachian basement sources are present in great

quantities in Permian–Cretaceous strata of the western U.S., though in the case of Jurassic-Cretaceous strata these signatures come from recycling of older sediment and not directly from the basement itself. Sandstone petrography can help resolve such complexities by searching for indicators of whether the source of the sediment is principally sedimentary (i.e., sedimentary rock fragments, quartz grains with recycled quartz overgrowths) or igneous and metamorphic basement (i.e., metamorphic and plutonic rock fragments). Also, comparing the detrital zircon age spectrum of a sample to reference spectra for potential sedimentary sources (e.g., Gehrels and Dickinson, 1995; Gehrels et al., 1995; Gehrels and Stewart, 1998; Stewart et al., 2001) can help to determine if the proximate source of the sediment is the basement which the age spectrum suggests or if it has been recycled through a tectonically distinct sedimentary unit.

## **Vita**

Glen Nelson Mackey, III was born in Roanoke, VA on May 14, 1981, the son of Nelson and Jean Mackey. After graduating from North Cross High School, Roanoke, VA in 1999, he entered the Johns Hopkins University in Baltimore, MD. He received the degrees of Bachelor of Arts in 1999. Upon graduating from Johns Hopkins University he served in the U.S. Army from 2003 until 2007. In August 2007, he began graduate studies at the University of Texas at Austin.

Permanent address: 1910 Greenwood Road, Roanoke, VA, 24015
